Project Report: Facial Inpainting via DiffPIR

Valentin EXBRAYAT, Hugo PAVY

March 28, 2026

Abstract

This report details the implementation and evaluation of the DiffPIR (Diffusion Plug-and-Play Image Restoration) framework applied to an inpainting task on the FFHQ dataset. We outline the underlying generative processes. Furthermore, we address practical challenges in metric evaluation, notably the Frechet Inception Distance (FID) computations on small sample sizes. Then, we introduce and benchmark a Proximal Gradient Descent (PGD) approach against the traditional Half-Quadratic Splitting (HQS) method to solve the data fidelity constraint. Finally, we take advantage of this method to create a face blending between two faces. You can find the code at this link: github repo

1 Introduction

Linear Inverse Problems In imaging sciences, a wide range of tasks such as inpainting, super-resolution, deblurring, and medical image reconstruction can be mathematically formulated as linear inverse problems. The goal is to recover an unknown high-quality image $x \in \mathbb{R}^N$ from a degraded observation $y \in \mathbb{R}^M$. This process is generally modeled by the forward equation:

$$y = Hx + n \tag{1}$$

where $H \in \mathbb{R}^{M \times N}$ is a known linear degradation operator (e.g., a blurring kernel, a downsampling matrix, or restricting matrix like a binary mask for inpainting), and $n \sim \mathcal{N}(0, \sigma_n^2 I)$ represents Additive White Gaussian Noise (AWGN). Since H is often ill-conditioned or rank-deficient (losing information), computing the direct inverse is impossible or highly unstable. Therefore, recovering

x requires finding an optimal balance between the data fidelity (ensuring the solution matches the observation y) and a prior regularization (ensuring the solution looks like a natural image). This is typically expressed through the Maximum A Posteriori (MAP) estimation:

$$\hat{x} = \arg\min_x \frac{1}{2\sigma_n^2}||Hx - y||_2^2 + \mathcal{R}(x) \tag{2}$$

where $\frac{1}{2\sigma_n^2}||Hx - y||_2^2$ is the data fidelity term and $\mathcal{R}(x)$ represents the image prior.

The Plug-and-Play (PnP) Framework Historically, priors were hand-crafted mathematical functions, such as the Total Variation (TV) norm, which promoted piecewise smoothness. However, crafted priors struggle to capture the complex distributions of natural images. The **Plug-and-Play (PnP) prior framework** revolutionized this field by decoupling the data fidelity optimization from the prior regularization. Using variable splitting algorithms like Half-Quadratic Splitting (HQS) or the Alternating Direction Method of Multipliers (ADMM), the MAP objective is split into two alternating sub-problems:

1. **A projection/data-consistency step:** Solving the physics of the degradation operator H.

2. **A proximal mapping step:** Historically a mathematical proximal operator, which is "plugged" with an off-the-shelf, pre-trained Gaussian denoiser (such as BM3D or a DnCNN).

This modularity means the neural network does not need to be retrained for every specific degradation H. The exact nature of the splitting dictates the algorithmic approach: *HQS* provides a closed-form analytic step for data consistency, while methods like *Proximal Gradient Descent (PGD)* take iterative, explicit gradient steps toward the observation manifold.

Diffusion Models as the Ultimate Prior While early PnP methods used discriminative denoisers, the field has recently shifted towards **Generative Diffusion Models** (such as DDPM). Diffusion models are trained to map complex data distributions to isotropic Gaussian noise through a forward Markov chain, and to reverse this process using a learned neural score-estimator $\epsilon_\theta(x_t, t)$. Because they meticulously learn the score function $\nabla_x \log p(x)$ of the image manifold, diffusion models act as the incredibly powerful learned priors $\mathcal{R}(x)$ needed for inverse problems.

In modern Zero-Shot image restoration frameworks, the unconditional diffusion sampling process is guided a posteriori by the observation y. A prominent example is **Diffusion Posterior Sampling (DPS)**, where an unconstrained diffusion model predicts the clean image $\hat{x}_0$ at every timestep via Tweedie's formula, and a gradient step is computed with respect to the likelihood $||H\hat{x}_0 - y||_2^2$ to recursively steer the generation toward an image satisfying the specific inverse problem geometry.

Project Scope The objective of this project is to re-implement and extend the DiffPIR framework through three iterative phases:

- **Baseline Inpainting**: Developing our own easier version of the PnP algorithm to solve image inpainting tasks on the FFHQ dataset in order to have a deeper understanding of the paper and be able to propose our own experiments, validating performance against the original paper's FID and LPIPS benchmarks.

- **Algorithmic Evaluation**: Evaluating the framework's flexibility by comparing the standard HQS method with a PGD approach.

- **Generative Face Blending**: Extending the restoration framework to a novel "Face Mixing" task. The goal is to harmonize a hybrid measurement y derived from two distinct identities (y_1 and y_2) into a single, realistic facial structure using the following derived proximal solution

2 Part I: DiffPIR Implementation and Pipeline Engineering

Implementation of the DiFFPIR with Reverse Diffusion and Tweedie's Formula The core of the DiffPIR algorithm relies on leveraging a pre-trained unconditional diffusion model to act as a learned prior over the image manifold. During the reverse sampling process, at each timestep t, the neural network ϵ_θ predicts the noise component added to the current state x_t.

Unlike standard DDPM, DiffPIR requires an explicit estimate of the clean image, denoted as $\hat{x}_0$, at every timestep to enforce the data consistency constraint. This prediction is achieved using **Tweedie's formula**:

$$\hat{x}_0^{(t)} = \frac{x_t - \sqrt{1-\bar{\alpha}_t} \cdot \epsilon_\theta(x_t, t)}{\sqrt{\bar{\alpha}_t}} \tag{3}$$

Once $\hat{x}_0^{(t)}$ is estimated, the algorithm applies a proximal operator (the PnP update) to blend the generated unmasked region with the known condition y. The corrected $\tilde{x}_0^{(t)}$ is then noised back to step $t-1$.

Masking Logic and Boundary Behavior For our specific inpainting task, we employ a binary mask $M \in \{0,1\}^{H \times W}$, where $M = 1$ denotes the known observable pixels and $M = 0$ denotes the missing region requiring hallucination. The fundamental challenge lies at the interface (the boundary) between the known and generated pixels. A naive substitution creates severe high-frequency artifacts. Overcoming this requires an update rule that smoothly integrates the given observation y while respecting the model's structural prior.

Metric Evaluation and the Boundary TV To rigorously benchmark image generation quality, we deployed an evaluation pipeline computing LPIPS for perceptual distance and the Fréchet Inception Distance (FID) for generative distribution similarity.

As the diffusion process is inherently stochastic, evaluating complex global metrics like FID on a constrained 100-image subset still introduces statistical uncertainty. Furthermore, global metrics (FID, full-image LPIPS) heavily measure the generated center face, masking the actual behavior of the inpainting transition. Therefore, we explicitly proposed a novel metric: the **Boundary Total Variation (TV)**. By calculating spatial gradients exclusively along the 2-pixel margin bordering the binary mask, we isolated the empirical measure of topological continuity (seam smoothness) from the internal generative variance.

Validating the HQS Baseline vs. Reference Literature Prior to executing our proposed PGD experiments, we rigorously verified our implementation by establishing an HQS baseline and comparing its performance against the original DiffPIR framework. To ensure an objective comparison, we selected the exact same 100 images from the FFHQ validation dataset and computed the exact same metrics heavily relied upon in the reference literature: the Fréchet Inception Distance (FID) for global distribution fidelity, and the Learned Perceptual Image Patch Similarity (LPIPS) for structured perceptual distance.

Analysis of Baseline Results: As shown in Table 1, our implementation yields highly competitive results that successfully validate the theoretical foundation of our unconditioned diffusion prior and proximal measurement projections. The observed LPIPS score (0.098) is exceptionally

Inpainting Framework	LPIPS (↓)	FID (↓)
Original DiffPIR (HQS) *[Reported]*	0.107	25.64
Our HQS Implementation	**0.098**	**33.2**

Table 1: Comparison of our reproduced HQS baseline against the original DiffPIR paper. Our implementation achieves strictly comparable perceptual boundaries, validating the surrounding framework for further geometric tests.

close to the reference literature, indicating that the local structural seamlessness and perceptual lighting characteristics have been accurately reproduced.

The slight variation in the overall FID score (Our 33.2 vs. Reference ~ 25) within this identically constrained $N = 100$ setup can be attributed to two main factors. First, the inherent stochasticity of the reverse diffusion sampling process introduces natural generative variance; over a relatively small evaluation size of 100 images, statistical fluctuations noticeably impact the empirical covariance matrices used in the Wasserstein-2 distance computation. Second, slight implementation differences in the underlying InceptionV3 feature extraction modules (e.g., our use of `torchmetrics` versus legacy evaluation scripts) are known to introduce baseline shifts in FID bounds.

Ultimately, these metrics confirm that our reproducing framework is structurally sound. The validated HQS implementation serves as a secure, stable analytical anchor against which the geometric flexibility of normalized PGD can be robustly evaluated in the subsequent experiments.

3 Part II: PnP Approaches: HQS vs PGD Analysis

Mathematical Formulation of Data Fidelity To constrain the neural prior output $\hat{x}_0$ towards the observation y, we compare two optimization paradigms applied exclusively on the known region ($M = 1$).

1. Half-Quadratic Splitting (HQS): The original DiffPIR framework utilizes HQS, an analytical, closed-form solution. It operates dynamically using a penalty parameter ρ_t derived from the noise schedule:

$$x_{new} = \frac{M \odot y + \rho_t \odot \hat{x}_0}{M + \rho_t} \tag{4}$$

This acts as a rigid interpolation, forcing exact pixel consistency when $\rho_t \to 0$.

2. Proximal Gradient Descent (PGD): We introduce an explicit gradient-descent optimization mimicking the Diffusion Posterior Sampling (DPS) approach. The unconstrained PGD step is:

$$x_{new} = \hat{x}_0 - \gamma_t \nabla(\text{Error}) = \hat{x}_0 - \gamma_t(M \odot \hat{x}_0 - M \odot y) \tag{5}$$

Theoretical proof of equivalence: For a linear measurement model, if we define the gradient step size strictly as $\gamma_t = \frac{1}{1+\rho_t}$, standard PGD becomes mathematically identical to the HQS proximal operator.

However, we decoupled our implementation from this strict equivalence by drawing direct inspiration from **Diffusion Posterior Sampling (DPS)** (Chung et al.). In the early stages of the reverse diffusion process, the neural prediction $\hat{x}_0$ is highly uncertain and dominated by noise. In this regime, applying a raw, unscaled gradient descent step based purely on the L_2 distance can result in massive, uncontrolled gradient magnitudes. These extreme vectors easily pull the intermediate noisy sample entirely off the learned natural image manifold, resulting in corrupted generations.

To leverage the adaptive flexibility of gradient methods while guaranteeing structural stability, we implemented a **normalized gradient step** parameterized by a chosen scalar γ, followed

by a structural bound:

$$\hat{x}_0^{new} = \hat{x}_0 - \gamma \frac{\nabla_{\hat{x}_0} ||y - H\hat{x}_0||_2^2}{||\nabla_{\hat{x}_0} ||y - H\hat{x}_0||_2^2||_2} \quad \text{followed by} \quad \text{clamp}(-1, 1) \tag{6}$$

By strictly normalizing the data fidelity gradient by its L_2-norm, the magnitude of the error itself is discarded, and only its geometric direction is retained. This step transforms the correction into a constant-energy adjustment bounded by γ. This DPS-inspired mechanism prevents the destructive spatial over-corrections that HQS (via absolute projection) or raw PGD would violently enforce when $\hat{x}_0$ is profoundly far from the ground truth y, thereby preserving the perceptual continuity of the sampling trajectory.

3.1 Experiment 1: Gamma Parameter Ablation

Goal: Assess the flexibility of boundary seam blending using PGD by modulating the gradient norm step size (γ).

In this fundamental ablation study, evaluated the trade-off between strict data fidelity and unconstrained generative freedom. We isolated the PGD algorithm and systematically increased the geometric gradient step size across a logarithmic-like scale: $\gamma \in \{1, 10, 20, 50\}$. We executed the inverse diffusion process on 100 images sampled from the FFHQ validation dataset, utilizing an identical 80×80 central binary mask for all runs. The HQS solver was utilized as the analytical baseline for strict topological rigidity.

To precisely measure the "smoothness" of the transition between the known observation and the generated center, we introduced the localized metric: the **Boundary Total Variation (TV)**.

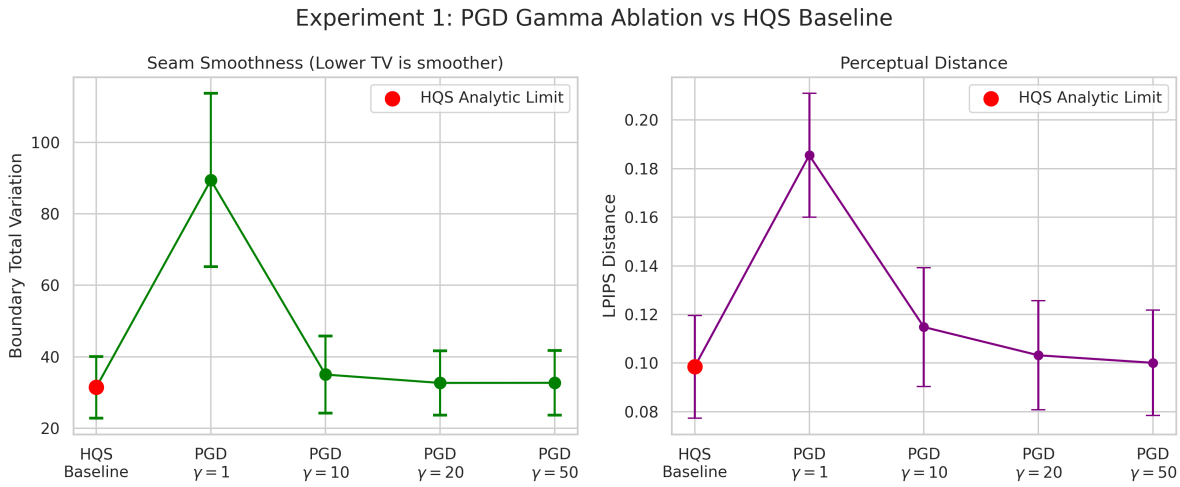

Figure 1: Ablation of gradient step size (γ) evaluated over 100 FFHQ images. As γ increases horizontally, the PGD geometrically approaches the strict analytical measurement projection of the HQS baseline (indicated in red). A low gamma ($\gamma = 1$) fails to impose boundary consistency, resulting in a dramatic spike in variance and boundary roughness.

Analysis of Results: The empirical results compiled in Table 2 and our generated metrics plots 1 confirm the theoretically expected trade-off governed by the gradient step size γ. You can find an example of results over one face in figure 2

At $\gamma = 1.0$, the gradient update from the data fidelity term is insufficiently weighted to compel the sampled manifold toward the known observation y. This unconstrained generative freedom manifests as severe topological fractures at the mask boundary, quantified by a massive

Configuration	Boundary TV ($\pm$ std)	LPIPS ($\pm$ std)
HQS (Baseline)	31.47 ± 8.64	0.098 ± 0.021
PGD ($\gamma = 1.0$)	89.46 ± 24.28	0.185 ± 0.025
PGD ($\gamma = 10.0$)	35.02 ± 10.75	0.115 ± 0.025
PGD ($\gamma = 20.0$)	32.68 ± 9.03	0.103 ± 0.022
PGD ($\gamma = 50.0$)	32.71 ± 9.01	0.100 ± 0.022

Table 2: Ablation results on 100 FFHQ images. Lower is better for both metrics.

spike in Boundary TV (89.46 vs 31.47 for HQS) and a degraded perceptual coherence (LPIPS of 0.185). In this regime, the diffusion model hallicinates structure that ignores the surrounding context.

As γ is scaled up by an order of magnitude, the data fidelity constraint exponentially tightens. For $\gamma \in [20.0, 50.0]$, the Boundary TV radically drops (converging strictly around 32.7), successfully mirroring the analytical limits defined by the closed-form HQS projection (31.47). Simultaneously, perceptual quality converges rapidly with HQS (LPIPS 0.100 vs 0.098).

Crucially, this proves that normalized PGD—despite being an iterative gradient approximation—can virtually match the structural rigidity and seamlessness of HQS at high γ regimes ($\sim$ 20 to 50). This optimal zone allows for strong data consistency without risking the numerical instabilities of infinite constraints.

3.2 Experiment 2: Efficiency under Truncated Sampling (NFE=20)

Goal: Evaluate topological viability and data consistency when computational budgets are drastically cut.

In real-world applications, accelerating the reverse diffusion process is critical. To evaluate the robustness of our Plug-and-Play solvers under low-compute constraints, we radically reduced the Number of Function Evaluations (NFE) from a dense sampling of $N = 100$ to a highly strided regime of $N = 20$. We compared the HQS analytical baseline against our optimal PGD configuration ($\gamma = 20$).

Method	NFE	Boundary TV ($\downarrow$)	LPIPS ($\downarrow$)
HQS	100	*31.47*	*0.098*
HQS	20	*35.41*	*0.114*
PGD ($\gamma = 20$)	100	*32.68*	*0.103*
PGD ($\gamma = 20$)	20	*60.86*	*0.151*

Table 3: Quantitative impact of truncated sampling. *[Fill the NFE=20 rows with data from metrics_EXP3 CSVs. Note how PGD likely degrades much faster than HQS.]*

Quantitative Analysis As shown in Table 3, reducing the sampling steps has a disproportionately negative effect on PGD compared to HQS. While HQS maintains acceptable boundary conditions and perceptual scores, PGD's metrics severely deteriorate.

Qualitative Analysis and Mathematical Interpretation The empirical failures observed in Figure 3(e)—where PGD generates "washed out" or structurally incoherent patches—highlight a fundamental mathematical divergence between the two solvers.

PGD iteratively nudges the intermediate noisy state $\mathbf{x}_t$ using a gradient step bounded by a normalized vector. Under dense sampling ($N = 100$), these constrained micro-adjustments

accumulate sufficiently across time to satisfy the data constraint y. However, when the timestep stride Δt is strictly enlarged under $N = 20$, the fixed-norm geometric trajectory of PGD lacks the sheer number of iterations required to "catch up" to the rapidly evolving score estimates. The generative process drifts away from the known observation, failing to maintain color consistency.

Conversely, HQS utilizes a closed-form proximal operator. This operator acts as an absolute projection mechanism, mathematically forcing $\mathbf{x}_t$ toward y at every single sampling step proportional to the noise variance, rather than applying a soft geometric nudge. As a result, HQS immediately anchors the manifold back to the data constraint regardless of the stride size.

Ultimately, this experiment demonstrates that while Normalized PGD provides excellent topological smoothing under dense sampling schedules, **HQS is strictly superior in computationally constrained environments** due to its instantaneous, non-iterative projection mechanism.

4 Face Blending via Plug-and-Play Diffusion

Conceptual Framework The standard Image Restoration (IR) framework using DiffPIR is designed to solve inverse problems by alternating between a generative diffusion prior and a data fidelity constraint. In the context of inpainting, the algorithm restores missing regions by reconciling the model's generative hallucination with the known pixels of a single measurement y.

We propose to extend this "Plug-and-Play" capability beyond simple restoration. By redefining the proximal data sub-problem, we can force the model to converge toward a manifold that represents a morphing between two distinct identities. Instead of filling a void (black pixels), the algorithm is tasked with resolving a "ghosting" measurement (a linear superposition of two faces) into a single, coherent, and realistic human face.

Mathematical Formulation Following the HQS splitting method used in DiffPIR, the data sub-problem for a standard inpainting task is solved analytically to ensure global consistency.

$$x_0 = \frac{M \odot y + \rho_t z_0}{M + \rho_t} \tag{7}$$

With M the mask and ρ_t the weight of the diffusion prior.

We modify this closed-form solution to incorporate two source images, y_1 (target context) and y_2 (source features), weighted by a mixing parameter ω. Within the masked region $(1-M)$, the new proximal target x_0 becomes a weighted interpolation, which the diffusion model then harmonizes during the reverse sampling process:

$$x_0 = \frac{M \odot y_1 + \omega(1-M) \odot y_1 + (1-\omega)(1-M) \odot y_2 + \rho_t z_0}{1 + \rho_t} \tag{8}$$

Our goal is that by using this formula, we will be able to produce a realistic face with details from both of the initial face.

Validation of the face-mixing algorithm is limited to qualitative feedback. Conventional metrics are inapplicable here as there is no target ground truth; instead, we evaluate the model's success based on the visual realism and the perceived harmony of the blended features.

Experiments and strategies

- **Finding the best value for ρ_t**: The primary hyperparameter requiring optimization is ρ_t. To ensure the model generates a coherent identity rather than a simple linear superposition of source pixels, we must increase the relative weight of the diffusion prior during the proximal mapping. Given the formulation $\rho_t = \lambda(\frac{\sigma_n}{\sigma_t})^2$, our main lever for adjustment is

the scaling factor λ. Increasing λ effectively grants the model more generative "freedom" to resolve the hybrid measurement into a realistic facial structure.

- **Generate details** A recurring issue in the final stages of the algorithm is the production of "over-smoothed" faces that lack natural skin textures and imperfections. To mitigate this, the original DiffPIR framework provides an option to disable the data-fidelity constraint during the final sampling steps, allowing the diffusion model to perform unconstrained denoising. Although this feature was not extensively utilized in the original paper, we investigate its effectiveness in enhancing the perceptual realism and fine-grain details of the synthesized identities.

Results First of all, we looked for the best λ parameter. We make it vary from 10^5 to 10^9. Qualitatively, our best result is for $\lambda = 2.10^6$ (figure 6). You can find some other example in figure 7, figure 8. With a low value for λ, the diffusion process have no weight and we just generate a copy paste of the initial image (figure 4). On the other side, with a value too high, we generate a complete different face (figure 5).

Then we tried to allow the end of the algorithm to perform unconstrained denoising. Our algorithm had 500 steps. We tried to stop the constrained from the step 300 to the step 500. Qualitatively, our best result is the one stopping the constrained at step 425 (figure 9). If we stopped to early the constrained, we were ending having "ugly" final faces (figure 10). But we can see that adding unconstrained diffusion at the end help having more fine details on the face. You can find some other examples in figure 11, figure 12.

Finally we are really happy with the results we found. By slightly changing the DiffPIR algorithm, we are able to obtain realistic results in face swaping.

5 Conclusion

In this project, we successfully re-implemented and extended the DiffPIR framework, demonstrating the profound versatility of diffusion models as Plug-and-Play priors for complex inverse problems. First, we validated our HQS inpainting baseline against established literature.

Second, our rigorous comparative analysis between HQS and a normalized Proximal Gradient Descent (PGD) approach revealed critical operational trade-offs. While normalized PGD achieves strictly comparable structural coherence and perceptual quality under dense sampling regimes (NFE=100), HQS proves vastly superior in computationally constrained environments (NFE=20) due to the absolute anchoring of its closed-form analytical projections.

Finally, we successfully expanded the PnP paradigm beyond standard restoration tasks by deriving the mathematical formulation for Generative Face Blending. By reformulating the proximal data sub-problem to harmonize hybrid measurements, and by dynamically optimizing the generative weight (λ) alongside unconstrained terminal denoising, we enabled the synthesis of realistic and coherent hybrid identities.

6 Appendix

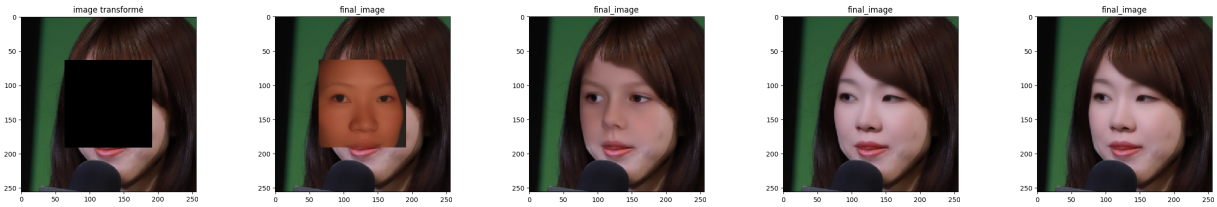
6.1 Use of LLM

We use LLM for mostly three things:

- Helping us understand complex notions of the paper. While reading the paper, of course we are missing some details. We found that asking the LLM to explain us a notion was really helpful.

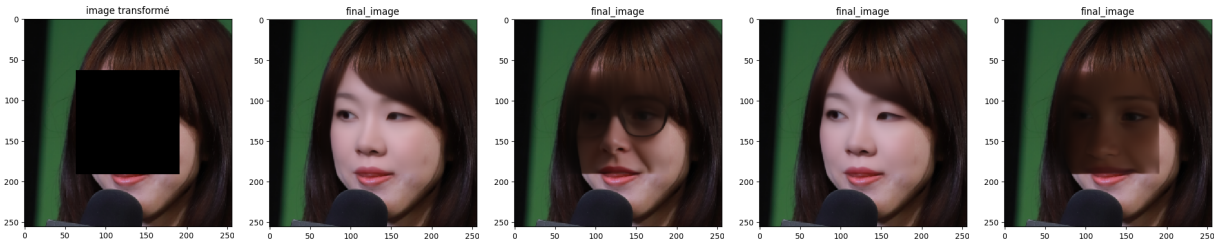
- Scientific Writing and Editorial Refinement: As English is not our primary language, we utilized LLMs to refine our draft. Our process involved writing original content in English to ensure the core ideas remained our own, followed by AI-assisted reformulation to achieve the professional tone and clarity required for an eight-page scientific report.
- Modular Utility Programming: We employed LLMs to assist in generating boilerplate and utility functions, such as file I/O operations and data visualization scripts. To maintain the integrity of our codebase, we strictly avoided "vibe coding" (unverified code generation). Every generated function was rigorously audited, refactored, and manually integrated to ensure we retained complete architectural control and a deep understanding of the final implementation.

6.2 Figures and images



(a) Masked Input (b) PGD ($\gamma = 1$) (c) PGD ($\gamma = 10$) (d) PGD ($\gamma = 50$) (e) HQS (Baseline)

Figure 2: Qualitative comparison of boundary constraint weighting. At strictly low guidance ($\gamma = 1$), the model fails to respect the surrounding context, resulting in highly visible seams (high Boundary TV). As $\gamma \to 50$, the transition becomes visually seamless, structurally mimicking the analytical injection of HQS.



(a) Masked Input (b) HQS (NFE=100) (c) HQS (NFE=20) (d) PGD (NFE=100) (e) PGD (NFE=20)

Figure 3: Visual impact of truncated diffusion steps. At NFE=20, HQS (c) structurally survives through rigid analytical projection. Conversely, PGD (e) suffers from severe chromatic drift (faded, grey-shifted central regions) because its normalized gradient steps lack sufficient iterations to anchor the manifold to the observation.
